**Abstract.** Object-oriented unit tests consist of sequences of method invocations. Behavior of an invocation depends on the method's arguments and the state of the receiver at the beginning of the invocation. Correspondingly, generating unit tests involves two tasks: generating method sequences that build relevant receiverobject states and generating relevant method arguments. This paper proposes Symstra, a framework that achieves both test generation tasks using symbolic execution of method sequences with symbolic arguments. We define symbolic states of object-oriented programs and novel ways to compare them. Given a set of methods from the class under test and a bound on the length of sequences, Symstra systematically explores the object-state space of the class and prunes this exploration based on the state comparisons. Experimental results show that Symstra generates unit tests that achieve higher branch coverage faster than the test-generation techniques based on concrete method arguments.

# 1 Introduction

Object-oriented unit tests are programs that test classes. Each test case consists of a fixed sequence of method invocations with fixed arguments that explores a particular aspect of the behavior of the class under test. Unit tests are becoming a key component of software development. The Extreme Programming discipline [5], for instance, leverages unit tests to permit continuous and controlled code changes. Unlike in traditional testing, it is developers (not testers) who should write tests for every aspect of the classes they develop. However, manual test generation is time consuming, and so typical unit test suites cover only some aspects of the class.

Since unit tests are gaining importance, many companies now provide tools, frameworks, and services around unit tests. Tools range from specialized test frameworks, such as JUnit [18] or Visual Studio's new team server [25], to automatic unit-test generation, such as Parasoft's Jtest [27]. However, existing test-generation tools typically do not provide guarantees about the generated unit-test suites. In particular, the suites rarely satisfy the branch-coverage test criterion [6], let alone a stronger criterion, such as the bounded intra-method path coverage [3] of the class under test. We present an approach that uses symbolic execution to exhaustively explore bounded method sequences of the class under test to generate tests that achieve high branch and intra-method path coverage.

#### 1.1 Background

Generating test sequences involves two tasks: generating method sequences that build relevant receiver-object state and generating relevant method arguments. This problem has been already addressed several times. Most tools generate test sequences using concrete representations. A popular approach is to use (smart) random generation; this approach is embodied in tools such as Jtest [27] (a commercial tool for Java) or JCrasher [13], Eclat [26], and JMLUnit [10] (three research prototypes for Java). Random tests are obviously neither minimal nor covering [35]. The AsmLT model-based testing tool [14, 16] uses concrete-state space-exploration techniques [12] to generate covering method sequences. But AsmLT requires the user to carefully choose sufficiently large concrete domains for method arguments and the right abstraction functions to guarantee the covering. Tools such as Korat [8] are able to generate non-isomorphic object graphs that can be used for testing, but they do not generate covering test sequences.

King proposed in the 70's to use symbolic execution for testing and verification [20]. But because of the high demands on constraint solvers, this technique did not get much attention for test generation until recently. For example, the BZTT tool uses constraint solving to derive method sequences from B specifications [22]. However, the B specifications are not object-oriented. Khurshid et al. [19,34] proposed an approach for generating tests for Java classes based on symbolic execution. They show that their generation based on symbolic execution generates tests faster than their model checking of method sequences with concrete arguments. This is expected: symbolic representations describe not only single states, but sets of states, and when applicable, symbolic representations can yield large improvements, witnessed for example by symbolic model checking [24]. The approach of Khurshid et al. [19,34], however, generates the receiver-object states, similar to Korat [8], only as object graphs, not through method sequences. Moreover, it requires the user to provide specially constructed class invariants [23], which effectively describe an over-approximation of the set of reachable object graphs.

Symbolic execution is the foundation of static code analysis tools. These tools typically do not generate test data, but automatically verify simple properties of programs. These properties often allow merging symbolic states that stem from different execution paths. However, for test generation, states have to be kept separate, since different tests should be used for different paths. Recently, tools such as SLAM [2,4] and Blast [7,17] were adapted for test generation. However, neither of them can deal with complex data structures, which are the focus of this paper.

#### 1.2 Contributions

This paper makes the following contributions.

**Symbolic Sequence Exploration:** We propose Symstra, a framework that uses symbolic execution to generate method sequences. When applicable, Symstra uses an exhaustive exploration of method sequences, similar to that of [14, 34, 35], but with symbolic variables for primitive-type arguments. Each symbolic argument represents a set of all possible concrete values for the argument. Symstra uses symbolic execution to operate on symbolic states that include symbolic variables.

Symbolic State Comparison: We present novel techniques for comparison of symbolic states of object-oriented programs. Our techniques allow Symstra to prune the

<sup>2</sup> Xie and Marinov and Schulte and Notkin

exploration of the object state and thus generate tests faster, without compromising the exhaustiveness of the exploration. In particular, the pruning preserves the intra-method path coverage of the generated test suites.

**Implementation:** We describe an implementation of a test-generation tool for Symstra. Our implementation handles the same constructs as the approach of Khurshid et al. [34], including dynamically allocated structures, method pre- and post-conditions, and symbolic data; however, our current implementation does not support concurrency. But we could reimplement Symstra in any Java model checker, such as Java Pathfinder [33] or Bogor [29], to also support concurrency.

**Evaluation:** We evaluate Symstra on seven subjects, most of which are complex data structures. The experimental results show that Symstra generates tests faster than the existing test-generation techniques based on exhaustive exploration of sequences with concrete method arguments [14, 16, 34, 35]. Further, given the same time for generation, Symstra can generate tests that achieve better branch coverage than the existing techniques. Finally, Symstra works on ordinary Java implementations and does not require the user to provide the additional methods that the approach of Khurshid et al. [34] requires.

### 2 Example

This section illustrates how Symstra explores method sequences and generates tests. Figure 1 shows a binary search tree class BST that implements a set of integers. Each tree has a pointer to the root node. Each node has an element and pointers to the left and right children. The class also implements the standard set operations: insert adds an element, if not already in the tree, to a leaf; remove deletes an element, if in the tree, replacing it with the smallest larger child if necessary; and contains checks if an element is in the tree. The class also has a default constructor that creates an empty tree.

Some tools such as Jtest [27], JCrasher [13] and Eclat [26], test a class by generating random sequences of methods; for BST, they could for example generate the following tests:

Test 1:	Test 2:
BST t1 = new BST();	BST t2 = new BST();
<pre>t1.insert(0);</pre>	t2.insert(2147483647);
t1.insert(-1);	t2.remove(2147483647);
<pre>t1.remove(0);</pre>	t2.insert(-2147483648);

Each test has a method sequence on the objects of the class, e.g., Test 1 creates a tree t1, invokes two insert methods on it, and then one remove. Typically, checking the correctness (of outputs) for such tests relies on design-by-contract annotations translated into run-time assertions [10, 27] or on model-based testing [16]. If there are no annotations or models, the tools check only the code robustness: execute the tests and check for uncaught exceptions [13].

Some other tools [14, 16, 34, 35] can exhaustively explore all method sequences up to a given length. Such exploration raises two questions: (1) what arguments to use for method calls, and (2) how to determine equivalent tests? These tools typically require the user to provide a sufficiently good set of concrete values for each argument, or based on the argument type, use a set of default values that may miss relevant behaviors. These

```
class BST implements Set {
   Node root;
   static class Node {
      int value;
      Node left;
      Node right;
   }
   void insert(int value) { ... }
   void remove(int value) { ... }
}
```

#### Fig. 1. A set implemented as a binary search tree

tools check equivalence of test sequences by comparing the states that the sequences build; the comparison uses either user-provided functions or defaults, such as identity or isomorphism. This generation is similar to explicit-state model checking [12].

Symstra also explores all sequences, but using symbolic values for primitive-type arguments in method calls. Such exploration relieves Symstra users from the burden of providing concrete values: Symstra determines the relevant values during the execution. Having symbolic arguments necessitates symbolic execution [20]. It operates on a symbolic state that consists of two parts: (1) a *constraint*, known as the *path condition*, that must hold for the execution to reach a certain point and (2) a heap that contains symbolic variables. When the symbolic execution encounters a branch, it explores both outcomes, appropriately adding the branch condition or its negation to the constraint. Symbolic state exploration in Symstra is conceptually similar to symbolic model checking [24].

Let us consider the symbolic execution of the following sequence:

```
BST t = new BST();
t.insert(x<sub>1</sub>);
t.insert(x<sub>2</sub>);
t.insert(x<sub>3</sub>);
t.remove(x<sub>4</sub>);
```

This sequence has four method calls whose arguments are symbolic variables  $x_1$ ,  $x_2$ ,  $x_3$ , and  $x_4$ . While an execution of a sequence with concrete arguments produces one state, symbolic execution of a sequence with symbolic arguments can produce several states, thus resulting in an execution tree. Figure 2 shows a part of the execution tree for this example. Each state has a heap and a constraint that must hold for that heap to be created. The constructor first creates an empty tree. The first insert then adds the element  $x_1$  to the tree.

The second insert produces states  $s_3$ ,  $s_4$ , and  $s_5$ : if  $x_1 = x_2$ , the tree does not change, and if  $x_2 > x_1$  (or  $x_2 < x_1$ ),  $x_2$  is added in the right (or left) subtree. Note that the symbolic states  $s_2$  and  $s_4$  are syntactically different:  $s_2$  has the constraint true, while  $s_4$  has  $x_1 = x_2$ . However, these two symbolic states are semantically equivalent: they can be instantiated into the same set of concrete heaps by giving to  $x_1$  and  $x_2$ concrete values that satisfy the constraints; since  $x_2$  does not appear in the heap in  $s_4$ , the constraint in  $s_4$  is "irrelevant". Instead of state equivalence, it suffices to check state subsumption: we say that  $s_2$  subsumes  $s_4$  because the set of concrete heaps of  $s_4$  is a subset of the set of concrete heaps of  $s_2$ . Hence, Symstra does not need to explore  $s_4$ after it has already explored  $s_2$ . Symstra detects this by checking that the implication of constraints  $x_1 = x_2 \Rightarrow$  true holds. Our current Symstra implementation uses the CVC Lite [11] theorem prover to check the validity of the implication. (Symstra checks it for universally quantified  $x_1$  and  $x_2$ , although  $x_2$  can be existentially quantified.)

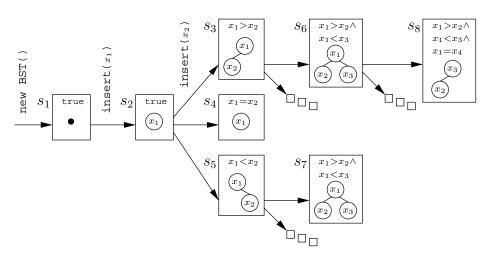

Fig. 2. A part of the symbolic execution tree

The third insert again produces several symbolic states. Symstra applies insert only on  $s_3$  and  $s_5$  (and not on  $s_4$ ). In particular, we focus on  $s_6$  and  $s_7$ , two of the symbolic states that these executions produce. These two states are syntactically different, but semantically equivalent: we can exchange the variables  $x_2$  and  $x_3$  to obtain the same symbolic state. Symstra detects this by checking that  $s_6$  and  $s_7$  are *isomorphic* (Section 3.2). Symstra finally applies remove. Note again that one of the symbolic states produced,  $s_8$ , is subsumed by a previously explored state,  $s_3$ .

This example has illustrated how Symstra would explore symbolic execution for one particular sequence. Symstra actually exhaustively explores the symbolic execution tree for all sequences up to a given length, pruning the exploration based on subsumption. These sequences consists of all specified methods of the class under test, i.e., insert, remove, and contains for BST.

After producing a symbolic state s, Symstra can generate a specific test with concrete arguments to produce a concrete heap of s. Symstra generates the test by traversing the shortest path from the root of the symbolic execution tree to s and outputting the method calls that it encounters. To generate concrete arguments for these calls, Symstra uses a constraint solver. Our current implementation uses the POOC solver [32]. The tests that it generates for  $s_3$  and  $s_4$  are:

Test for s3:	Test for s4:
BST t3 = new BST();	BST t4 = new BST();
t3.insert(-999999);	t4.insert(-1000000);
t3.insert(-1000000);	t4.insert(-1000000);

# **3** Framework and Implementation

This section formalizes the notions introduced informally in the previous section. We first describe how Symstra represents symbolic states. Symstra uses them for two purposes: (1) during the symbolic execution of method invocations and (2) for representing the states between method invocations in method sequences. We then present how Symstra compares states based on the isomorphism of heaps and implication of constraints.

We next present the symbolic execution of method invocations. We finally present the systematic exploration of method sequences and how Symstra uses symbolic state comparison to prune this exploration. We present the Symstra technique itself as well as our current implementation.

#### 3.1 Symbolic State

Symbolic states differ from concrete states, on which the usual program executions operate, in that symbolic states contain symbolic expressions with symbolic variables and also constraints on these variables [20]. Symstra uses the following symbolic expressions and constraints:

- A symbolic variable is a symbolic expression. Each symbolic variable has a type, which is one of the Java types. For example,  $x_1$  and  $x_2$  may be each a symbolic variable (and thus also a symbolic expression) of type int.
- · A Java constant of some type is a symbolic expression of that type.
- For each Java operator  $\odot$  with *n* operands, *n* symbolic expressions of the appropriate operand types connected with  $\odot$  are a symbolic expression of the result type. For example,  $x_1 + x_2$  and  $x_1 > x_2$  are expressions of type int and boolean, respectively.
- · Symbolic expressions of type boolean are constraints.

Let P be the set of all primitive values, including integers, true, false, etc. Let V be a set of infinite number of symbolic variables of each type and U a set of all possible expressions formed from V and P. Given a valuation for the variables,  $\eta : V \to P$ , we extend it to evaluate all expressions  $\eta : U \to P$  as follows:  $\eta(p) = p$  for all  $p \in P$ , and  $\eta(\bigcirc u_1, \ldots, u_n) = \text{eval}(\bigcirc, \eta(u_1), \ldots, \eta(u_n))$  for all  $u_1, \ldots, u_n \in U$  and operations  $\bigcirc$ , where eval evaluates operations on primitive values according to the Java semantics.

In object-oriented programs, a concrete state consists of a global heap and a stack (in general one stack for each thread, but we consider here only single-threaded programs), as well as several other parts, such as metadata for classes and program counters. Symbolic states in Symstra have the same parts as concrete states, but the heaps and stacks in symbolic states can contain symbolic expressions; additionally, each symbolic state has a constraint. We focus on the symbolic state between method sequences.

### **Definition 1.** A symbolic state $\langle C, H \rangle$ is a pair of a constraint and a symbolic heap.

We view each heap as a graph: nodes represent objects and edges represent fields. Let O be some set of objects whose fields form a set F. Each object has a field that represents its class. We consider arrays as objects whose fields are labelled with (integer) array indexes and point to the array elements.

**Definition 2.** A symbolic heap is an edge-labelled graph  $\langle O, E \rangle$ , where  $E \subseteq O \times F \times (O \cup \{ \texttt{null} \} \cup U)$  such that for each field f of each  $o \in O$  exactly one  $\langle o, f, o' \rangle \in E$ . A concrete heap has only concrete values:  $o' \in O \cup \{\texttt{null} \} \cup P$ .

### 3.2 Heap Isomorphism

We define heap isomorphism as graph isomorphism based on node bijection [8]. We are interested in detecting isomorphic heaps because they lead to equivalent method

<sup>6</sup> Xie and Marinov and Schulte and Notkin

behaviors, and it is thus sufficient to explore only one representative from each isomorphism partition. Nodes in symbolic heaps contain symbolic variables, so we first define renaming of symbolic variables. Given a bijection  $\tau : V \to V$ , we extend it homomorphically to the whole  $\tau : U \to U$  as follows:  $\tau(p) = p$  for all  $p \in P$ , and  $\tau(\odot u_1, \ldots, u_n) = \odot \tau(u_1), \ldots, \tau(u_n)$  for all  $u_1, \ldots, u_n \in U$  and operations  $\odot$ .

**Definition 3.** Two heaps  $\langle O_1, E_1 \rangle$  and  $\langle O_2, E_2 \rangle$  are isomorphic iff there are bijections  $\rho: O_1 \to O_2$  and  $\tau: V \to V$  such that:

$$\begin{split} E_2 &= \{ \langle \rho(o), f, \rho(o') \rangle | \langle o, f, o' \rangle \in E_1, o' \in O_1 \} \cup \{ \langle \rho(o), f, \texttt{null} \rangle | \langle o, f, \texttt{null} \rangle \in E_1 \} \cup \\ \{ \langle \rho(o), f, \tau(o') \rangle | \langle o, f, o' \rangle \in E_1, o' \in U \}. \end{split}$$

Note that the definition allows only object identities and symbolic variables to vary: two isomorphic heaps have the same fields for all objects and equal (up to renaming) symbolic expressions for all primitive fields.

The state exploration in Symstra focuses on the state of several objects and does not consider the entire heap; in this context, the state of an object o consists of the values of the fields of o and fields of all objects *reachable* from o. From a program heap  $\langle O, E \rangle$  and a tuple  $\langle v_0, \ldots, v_n \rangle$  of pointers and symbolic expressions  $v_i \in O \cup U$ , where  $0 \le i \le n$ , Symstra constructs a *rooted heap* [35]  $\langle O_h, E_h \rangle$  that has a unique root object  $r \in O_h$ : Symstra first creates the heap  $\langle O', E' \rangle$ , where  $O' = O \cup \{r\}$ ,  $r \notin O$ , and  $E' = E \cup \{\langle r, i, v_i \rangle | 0 \le i \le n\}$ , and then creates  $\langle O_h, E_h \rangle$  as the subgraph of  $\langle O', E' \rangle$  such that  $O_h \subseteq O'$  is the set of all objects reachable from r and  $E_h = \{\langle o, f, o' \rangle \in E' | o \in O_h\}$ .

We can efficiently check isomorphism of rooted heaps, even though for general graphs it is unknown whether checking isomorphism can be done in polynomial time. Symstra *linearizes* heaps into integer sequences such that checking heap isomorphism corresponds to checking sequence equality. Figure 3 shows the linearization algorithm. It starts from the root and traverses the heap depth first. It assigns a unique identifier to each object, keeps this mapping in objs and reuses it for objects that appear in cycles. It also assigns a unique identifier to each symbolic variable, keeps this mapping in vars and reuses it for variables that appear several times in the heap.

A similar linearization is used to represent concrete heaps in model checking [1,30, 33]. This paper extends the linearization from our previous work [35] with linSymExp that handles symbolic expressions; this improves on the approach of Khurshid et al. [19, 34] that does not use any comparison for symbolic expressions. It is easy to show that our linearization normalizes rooted heaps.

**Theorem 1.** Two rooted heaps  $\langle O_1, E_1 \rangle$  (with root  $r_1$ ) and  $\langle O_2, E_2 \rangle$  (with root  $r_2$ ) are isomorphic iff linearize  $(r_1, \langle O_1, E_1 \rangle)$ =linearize  $(r_2, \langle O_2, E_2 \rangle)$ .

#### 3.3 State Subsumption

We define symbolic state subsumption based on the concrete heaps that each symbolic state represents. Symstra uses state subsumption to prune the exploration. To instantiate a symbolic heap into a concrete heap, we replace the symbolic variables in the heap with primitive values that satisfy the constraint in the symbolic state.

8

```
Map<Object, int> objs; // maps objects to unique ids
Map<SymVar, int> vars; // maps symbolic variables to unique ids
int[] linearize(Object root, Heap <0,E>) {
  objs = new Map(); vars = new Map();
  return lin(root, <0,E>>;
int[] lin(Object root, Heap <0,E>) {
  if (objs.containsKey(root))
   return singletonSequence(objs.get(root));
  int id = objs.size() + 1; objs.put(root, id);
  int[] seq = singletonSequence(id);
  Edge[] fields = sortByField({ <root, f, o> in E });
  foreach (<root, f, o> in fields) {
    if (isSymbolicExpression(o)) seq.append(linSymExp(o));
    elseif (o == null) seq.append(0);
    else seq.append(lin(o, <0,E>)); // pointer to an object
  return seq;
}
int[] linSymExp(SymExp e) {
  if (isSymVar(e)) {
    if (!vars.containsKev(e))
     vars.put(e, vars.size() + 1);
   return singletonSequence(vars.get(e));
  } elseif (isPrimitive(e)) return uniqueRepresentation(e);
  else { // operation with operands
    int[] seq = singletonSequence(uniqueRepresentation(e.getOperation()));
    foreach (SymExp e' in e.getOperands())
     seq.append(linSymExp(e'));
   return seq;
}
```

Fig. 3. Pseudo-code of linearization for a symbolic rooted heap

**Definition 4.** An instantiation  $\mathcal{I}(\langle C, H \rangle)$  of a symbolic state  $\langle C, H \rangle$  is a set of concrete heaps H' such that there exists a valuation  $\eta : V \to P$  for which  $\eta(C)$  is true and H'is the evaluation  $\eta(H)$  of all expressions in H according to  $\eta$ .

**Definition 5.** A symbolic state  $\langle C_1, H_1 \rangle$  subsumes another symbolic state  $\langle C_2, H_2 \rangle$ , in notation  $\langle C_1, H_1 \rangle \supseteq \langle C_2, H_2 \rangle$ , iff for each concrete heap  $H'_2 \in \mathcal{I}(\langle C_2, H_2 \rangle)$ , there exists a concrete heap  $H'_1 \in \mathcal{I}(\langle C_1, H_1 \rangle)$  such that  $H'_1$  and  $H'_2$  are isomorphic.

Checking semantically whether one state subsumes another is very expensive. Instead, Symstra uses the algorithm in Figure 4 to check if the constraint of  $\langle C_1, H_1 \rangle$ , after suitable renaming, implies the constraint of  $\langle C_2, H_2 \rangle$ . We can show that this algorithm is a conservative approximation of subsumption.

**Theorem 2.** If checkSubsumes( $\langle C_1, H_1 \rangle$ ,  $\langle C_2, H_2 \rangle$ ) then  $\langle C_1, H_1 \rangle$  subsumes  $\langle C_2, H_2 \rangle$ .

Symstra gains the power and inherits the limits from the technique used to check the implication on the (renamed) constraints. The current Symstra prototype uses the CVC Lite [11] automatic theorem prover, which has decision procedures for several constraints, including real linear arithmetic, uninterpreted functions, arrays etc. Since these checks can consume a lot of time, Symstra further uses the following conservative approximation: if variables( $C_1$ ) are not a subset of variables( $\tau(C_2)$ ), return false without checking the implication.

Fig. 4. Pseudo-code of subsumption checking for symbolic states

#### 3.4 Symbolic Execution

We next discuss the symbolic execution of one method in a method sequence. Each method execution starts with one symbolic state and produces several symbolic states. We use the notation  $\sigma_m(\langle C, H \rangle)$  to denote the set  $\{\langle C_1, H_1 \rangle, \ldots, \langle C_n, H_n \rangle\}$  of states that the symbolic execution,  $\sigma$ , of the method m produces starting from the state  $\langle C, H \rangle$ .

Appendix A presents a symbolic execution for a fragment of Java. As other symbolic executions [20,34], it symbolically explores both branches of  $i \neq$ statements, modifying the constraint with a conjunct that needs to hold for the execution to take a certain branch. In this context, the constraint is called *path condition*, because it is a conjunction of conditions that need to hold for the execution to take a certain path and reach the current address. This symbolic execution directly explores every path of the method under consideration. The common issue in the symbolic execution is that the number of paths may be infinite and thus  $\sigma_m(\langle C, H \rangle)$  may be unbounded. In such cases, Symstra can use the standard set of heuristics to explore only some of the paths [9, 34].

The current Symstra prototype implements the execution steps on symbolic state by rewriting the code to operate on symbolic expressions. Further, Symstra implements the exploration of different branches by re-executing the method from the beginning for each path, without storing any intermediate states. Our stateless [15] implementation, although less optimized, turned out to be at least an order of magnitude faster than the more optimized Java Pathfinder model checker [33, 34] that stores the states and thus does not re-execute the methods from the beginning. Note that Symstra re-executes only one method (for different paths), not the whole method sequence.

Our Symstra prototype also implements the standard optimizations for symbolic execution. First, Symstra simplifies the constraints that it builds at branches; specifically, before conjoining the path condition so far C and the current branch condition C' (where C' is S(l) or !S(l), using the notation from Appendix A), Symstra checks if some of the conjuncts in C implies C'; if so, Symstra does not conjoin C'. Second, Symstra checks if the constraint C&&C' is unsatisfiable; if so, Symstra stops the current path of symbolic execution, because it is an infeasible path. The current Symstra prototype can use the CVC Lite [11] theorem prover or the Omega library [28] to check unsatisfiability. We have found that Omega is faster, but it handles only linear arithmetic constraints.

#### 3.5 Symbolic State Exploration

We next present the symbolic state space for method sequences and how Symstra systematically explores this state space. The state space consists of all states that are reach-

9

able with the symbolic execution of all possible method sequences for the class under test. Let  $\mathcal{C}/\mathcal{M}$  be a set of the constructor/non-constructor methods of this class. Each method sequence starts with a constructor from  $\mathcal{C}$  followed by several methods from  $\mathcal{M}$ . We denote with  $\Sigma_{\mathcal{C},\mathcal{M}}$  the state space for these sequences. The initial symbolic state is  $s_0 = \langle \text{true}, \{\} \rangle$ : the constraint is true, and the heap is empty. The state space includes the states that the symbolic execution produces for the constructors and methods:  $\bigcup_{c \in \mathcal{C}} \sigma_c(s_0) \subset \Sigma_{\mathcal{C},\mathcal{M}}$  and  $\forall s \in \Sigma_{\mathcal{C},\mathcal{M}}$ .  $\bigcup_{m \in \mathcal{M}} \sigma_m(s) \subset \Sigma_{\mathcal{C},\mathcal{M}}$ . As usual [12],  $\Sigma_{\mathcal{C},\mathcal{M}}$  is the least fixed point of these equations. The state space is typically infinite.

The current Symstra prototype exhaustively explores a bounded part of the symbolic state space in a breadth-first manner. The inputs to Symstra are a set of constructor C and non-constructor methods  $\mathcal{M}$  of the class under test and a bound on the length of sequences. A set of symbolic states is *subsumption-free* if no symbolic state from the set is subsumed by another. Symstra maintains a subsumption-free set of explored states and a processing queue of states. Symstra processes the queue in a breadth-first manner: it takes one state and symbolically executes each method under test (constructor at the beginning of the sequence and a non-constructor after that) for each path on this state. Every such execution yields a new symbolic state. Symstra adds the new state to the queue for further exploration only if it is not subsumed by an already explored state from the set. Otherwise, Symstra prunes the exploration: the new symbolic state represents only a subset of the concrete heaps that some explored symbolic state represents; it is thus unnecessary to explore the new state further. Pruning based on subsumption plays the key role in enabling Symstra to explore large state spaces.

#### 3.6 Concrete Test Generation

During the symbolic state exploration, Symstra also builds specific concrete tests that lead to the explored states. Whenever Symstra finishes a symbolic execution of a method that generates a new symbolic state  $\langle C, H \rangle$ , it also generates a *symbolic test*. This test consists of the constraint C and the shortest method sequence that reaches  $\langle C, H \rangle$ . (Symstra associates such a method sequence with each symbolic state and dynamically updates it during execution). Symstra then instantiates a symbolic test using the POOC constraint solver [32] to solve the constraint C over the symbolic arguments for methods in the sequence. Based on the produced solution, Symstra obtains concrete arguments for the sequence leading to  $\langle C, H \rangle$ . Symstra exports such concrete test sequences into a JUnit test class [18]. It also exports the constraint C associated with the test as a comment for the test in the JUnit test class.

At the class-loading time, Symstra instruments each branching point of the class under test for measuring branch coverage at the bytecode level. It also instruments each method of the class to capture uncaught exceptions at runtime. The user can configure Symstra to select only those generated tests that increase branch coverage or throw new uncaught exceptions.

### 4 Evaluation

This section presents our evaluation of Symstra for exploring method sequences and generating tests. We compare Symstra with Rostra [35], our previous framework that

Table 1. Experimental subjects

generates tests using bounded-exhaustive exploration of sequences with concrete arguments. We have developed Symstra on top of Rostra, so that the comparison does not give an unfair advantage to Symstra because of unrelated improvements. We have performed the experiments on a Linux machine with a Pentium IV 2.8 GHz processor using Sun's Java 2 SDK 1.4.2 JVM with 512 MB allocated memory.

Table 1 lists the seven Java classes that we use in the experiments. The first six classes were previously used in evaluating Rostra [35], and the last five classes were used in evaluating Korat [8]. The columns of the table show the class name, the public methods under test (that the generated sequences consist of), some private methods invoked by the public methods, the number of non-comment, non-blank lines of code in all those methods, and the number of branches for each subject.

We use Symstra and Rostra to generate test sequences with up to the N methods. Rostra also requires concrete values for arguments, so we set it to use N different arguments (the integers from 0 to N - 1) for methods under test. (The same experimental setup was used for generating test sequences with the Java Pathfinder model checker [34].) Table 2 shows the comparison between Symstra and Rostra. We range Nfrom five to eight. (For N < 5, both Symstra and Rostra generate tests really fast, usually within a couple of seconds, but those tests do not have good quality.) We tabulate the time to generate the tests (measured in seconds, Columns 3 and 7), the number of explored symbolic and concrete object states (Columns 4 and 8), the number of generated tests (Columns 5 and 9), and the branch coverage achieved by the generated tests and, in the parentheses, the cumulative number of tests that increase branch coverage.

During test generation, we set a three-minute timeout for each iteration of the breadth-first exploration: when an iteration exceeds three minutes, the exhaustive exploration of Symstra or Rostra is stopped and the system proceeds with the next iteration. We use a "\*" mark for each entry where the test-generation process timed out; the state exploration of these entries is no longer exhaustive. We use a "-" mark with to denote an entry where Symstra or Rostra exceeded the memory limit.

The results indicate that Symstra generates method sequences of the same length N often much faster than Rostra, thus enabling Symstra to generate longer method sequences within a given time limit. Both Symstra and Rostra achieve the same branch coverage for method sequences of the same length N. However, Symstra achieves higher coverage faster. It also takes less memory and can finish generation in more

		Symstra		Rostra

Table 2. Experimental results of test generation using Symstra and Rostra

cases than Rostra. These results are due to the fact that each symbolic state, which Symstra explores at once, actually describes a set of concrete states, which Rostra must explore one by one. Rostra often exceeds the memory limit when N = 7 or N = 8, which is often not enough to guarantee full branch coverage.

Visser et al. [34] generate tests based on exhaustive exploration of sequences with concrete method arguments by using the Java Pathfinder model checker [33]. Based on their published results [34], even Rostra explores method sequences with concrete method arguments faster than Java Pathfinder. But they can handle multi-threading. We believe that adding Symstra-like symbolic method sequences to Java Pathfinder would significantly improve test generation using Java Pathfinder.

# 5 Discussion

*Specifications*. Symstra leverages specifications, i.e. method pre- and post-conditions and class invariants, written in the Java Modelling Language (JML) [21]. The JML tool-set transforms these constructs into run-time assertions that throw JML-specific

13

exceptions when violated. Generating method sequences for methods with JML specifications amounts to generating *legal* method sequences that satisfy pre-conditions and class invariants, i.e., do not throw exceptions for these constructs. If during the exploration Symstra finds a method sequence that violates a post-condition or invariant, Symstra has discovered a bug; Symstra can be configured to generate such tests and continue or stop test generation. If a class implementation is correct with respect to its specification, paths that throw post-condition or invariant exceptions should be infeasible.

Symstra operates on the bytecode level. It can perform testing of the specifications woven into method bytecode by the JML tool-set or by similar tools. Note that in this setting Symstra essentially uses black-box testing [34] to explore only those symbolic states that are produced by method executions that satisfy pre-conditions and class invariants; conditions that appear in specifications simply propagate into the constraints associated with a symbolic state explored by Symstra. Using symbolic execution, Symstra thus obtains the generation of legal test sequences "for free".

*Performance.* Symstra enables exploring longer method sequences than the techniques based on concrete arguments. However, users may want to have an exploration of even longer sequences to achieve some test purpose. In such cases, the users can apply several techniques that trade the guarantee of the intra-method path coverage for longer sequences. For example, the user may provide abstraction functions for states [23], as used for instance in the AsmLT generation tool [14], or binary methods for comparing states (e.g. equals), as used for instance in Rostra. Symstra can then generate tests that instead of subsumption use these user-provided functions for comparing state. This leads to a potential loss of intra-method path coverage but enables faster, user-controlled exploration. To explore longer sequences, Symstra can also use standard heuristics [9, 34] for selecting only a set of paths instead of exploring all paths.

*Limitations*. The use of symbolic execution has inherent limitations. For example, it cannot precisely handle array indexes that are symbolic variables. This situation occurs in some classes, such as DisjSet and HashMap used previously in evaluating Rostra [35]. One solution is to combine symbolic execution with (exhaustive or random) exploration based on concrete arguments: a static analysis would determine which arguments can be symbolically executed, and for the rest, the user would provide a set of concrete values [14].

So far we have discussed only methods that take primitive arguments. We cannot directly transform non-primitive arguments into symbolic variables (of primitive type). However, we can use the standard approach for generating such arguments: generate them also as sequences of method calls that may recursively require more sequences of method calls, but eventually boil down to primitive values. JCrasher [13] and Eclat [26] take a similar approach. Another solution is to transform these arguments into reference-type symbolic variables and enhance the symbolic execution.

## 6 Conclusion

Automatic generation of unit tests is an important topic. We have proposed Symstra, a novel framework that uses symbolic execution to generate a small number of method

sequences for complex data structures that reach high branch and intra-method path coverage. Symstra exhaustively explores method sequences with symbolic arguments up to a given length. It prunes the exploration based on state subsumption and this pruning enables to generate tests faster but without compromising the exhaustiveness of the exploration. We have implemented a test-generation tool for Symstra and evaluated Symstra on seven subjects, most of which are complex data structures. The results show that Symstra generates tests faster than the existing test-generation techniques based on exhaustive exploration of sequences with concrete method arguments, and given the same time limit, Symstra can generate tests that achieve better branch coverage than these existing techniques.

### A Symbolic Execution

This section presents details of the symbolic execution of one Java method. Each execution of a method m starts with one symbolic state  $\langle C, H \rangle$  and produces several symbolic states  $\sigma_m(\langle C, H \rangle)$ . At the beginning of the execution, the state  $\langle C, H \rangle$  is transformed into an *extended symbolic state*  $\langle C, H, S, R \rangle$ , which contains a symbolic stack S with only one frame with fresh symbolic variables for all arguments and conceptually the rest of the concrete state R. In general, for each thread there is one symbolic stack that maps

each local variable into a symbolic expression of the corresponding type. The symbolic execution operates on this extended state following [20] for representing values with symbolic expressions. We define the symbolic execution as a function,  $\sigma$ , whose inputs are an extended symbolic state and an address of the next instruction to execute (and implicitly a program to execute), and whose output is a set of extended symbolic states. Each of the extended states in the output has the empty stack and is transformed into a non-extended state by dropping S and R to form  $\sigma_m(\langle C, H \rangle)$ .

We adopt the model from Salcianu [31] and consider that the code is in a form similar to Java's bytecode, i.e., each method consists of a list of simple instructions. Each instruction is at some address a in this list. Different kinds of instructions and their concrete semantics are given in [31][Section 4.1].

Instruction at a	$\sigma(\langle C, H, S, R \rangle, a)$
Constant $l = p$	$\sigma(\langle C,H,S[l\mapsto \operatorname{SymExp}(p)],R\rangle,a+1)$
Operation $l = \bigcirc l_1 \dots l_j$	$\sigma(\langle C, H, S[l \mapsto \text{SymExp}(\odot, S(l_1), \dots, S(l_j))], R\rangle, a+1)$ where $\odot$ is a Java operator, such as +, -, ==, >, &&
Load $l_1 = l_2 \cdot f$	$\sigma(\langle C, H, S[l_1 \mapsto H(S(l_2), f)], R \rangle, a+1)$
Store $l_1 \cdot f = l_2$	$\sigma(\langle C, H[(S(l_1), f) \mapsto S(l_2)], S, R \rangle, a+1)$
New l = new C	$\sigma(\langle C, H \cup \{\langle o, f, \text{default}(f) \rangle   f \in \text{fields}(C)\}, S[l \mapsto o], R' \rangle, a+1)$ where $o \notin H; R'$ may include some new data about the class C
Call $l_R = l_0 \cdot \mathbf{m} (l_1, \dots, l_j)$	$\sigma(\langle C, H, \text{push-frame}(S, a, l_R, S(l_1), \dots, S(l_j)), R \rangle, \text{start}(m))$
Return return l	$\sigma(\langle C, H, pop-frame(S)[retloc(S) \mapsto S(l)], R\rangle, retadd(S))$
If if ( <i>l</i> ) goto $a'$	$\sigma(\langle C\texttt{k\&!}S(l),H,S,R\rangle,a+1)\cup\sigma(\langle C\texttt{k\&}S(l),H,S,R\rangle,a')$

Table 3. Symbolic execution for different kinds of instructions

Table 3 presents the symbolic execution for the relevant kinds of instructions. It shows how to evaluate  $\sigma(\langle C, H, S, R \rangle, a)$  based on the kind of the instruction at address a. For Constant, Operation, and Load,  $\sigma(\langle C, H, S, R \rangle, a) = \sigma(\langle C, H, S', R \rangle, a + 1)$ , where S' is the appropriately modified stack, and a + 1 is the address of the next instruction. For Store only the heap is modified, and for New both the heap and the stack are modified to include the new object o whose fields have default values. For Call and Return, the stack is modified as usual by pushing a new frame (and initializing the formal arguments with the actual arguments) and popping the top frame, respectively. The most interesting case is for If: symbolic execution explores both branches, because the condition is a symbolic expression that may be true or false for different valuations of symbolic variables. The execution of if also modifies the constraint with a conjunct that needs to hold for the execution to take a certain branch.
